Direct vancomycin irrigation as treatment for resistant aortic bed infection

Hannah Winter, Isaac Nyamekye

ABSTRACT

Introduction: A case report of direct vancomycin irrigation as management of retroperitoneal abscess following removal of infected aortic graft. Case Report: A 63-year-old man presented nine years following aortic aneurysm repair with recurrence of aneurysm. At re-operation, aortic graft infection was diagnosed and managed with graft excision, debridement, axillo-bifemoral bypass and prolonged systemic antibiotics. The abscess failed to resolve. Direct vancomycin irrigation via percutaneous drainage catheter led to resolution of infection. Conclusion: There is little evidence to support vancomycin irrigation as treatment after removal of infected aortic grafts. Such an approach may be considered in patients failing to respond to traditional therapy.

Keywords: Vancomycin, Irrigation, Graft infection, Aneurysm, Aortic graft

INTRODUCTION

Prosthetic graft infection is a recognised complication of aortic aneurysm surgery carrying a high morbidity and mortality [1]. Treatment of prosthetic graft infection has traditionally included excision of the infected prosthesis, extra-anatomical bypass and prolonged treatment with systemic antibiotics. We report a novel approach of treating persistent retroperitoneal abscess formation complicating aortic graft infection.

CASE REPORT

A 63-year-old man presented to his local accident and emergency department nine years following combined coronary bypass and infra-renal aortic aneurysm repair. He complained of abdominal pain radiating through to his back but remained hemodynamically stable. His comorbidities included a previous smoking habit, medicated hypertension and angina. Examination revealed a tender large aortic aneurysm. An urgent Computed Tomography (CT) scan demonstrated a 9.5 cm infra-renal abdominal aneurysm with contrast outside of the old graft but within the sac (Figure 1). He was transferred to our vascular unit and taken to theatre for repair of a false aneurysm. On opening the sac frank pus was encountered alongside the old Dacron graft and a disruption to the proximal anastomosis line. Pus was sent for microbiology, the aortic graft excised and the ends of

native aorta over sewn. The aortic bed was radically debrided and an omental patch sutured to the anterior spinous ligament. An axillo-bifemoral bypass was placed from the right using a polytetrafluoroethylene (PTFE) graft (Figure 2). Perioperative vancomycin, cefuroxime and metronidazole were continued intravenously for two weeks.

No organisms were isolated from the pus contents. The patient made a good recovery and was discharged home on day 16 with a six week course of oral co-amoxiclav and metronidazole following microbiology advice.

Abdominal ultrasonogram (USG) performed one month after discharge revealed no untoward abnormality. However, patient was re-admitted after two months with pyrexia of 39°C, rigors, back pain and a raised C-reactive protein of 266 mg/L, but a normal white cell count. An intravenous cocktail of cefuroxime, vancomycin, metronidazole and gentamicin was commenced on microbiology advice. CT imaging revealed a 6x4x7 cm low attenuation area in the aortic bed suggestive of abscess formation. A white cell localisation scan was unremarkable. Turbid yellow retroperitoneal fluid was drained from the aortic bed under CT guidance. No organisms were isolated and blood cultures were negative.

Despite two weeks of intravenous antibiotics the patient continued to have spikes of high temperature and further imaging revealed recurrence of the retroperitoneal collection. A pigtail catheter was placed for drainage. After completion of drainage the catheter was used to instil 1 g of vancomycin diluted in 50 ml 0.9% saline directly into the retroperitoneal space by placing the bag on a drip stand. The bag was clamped for two hours and then drained by placing it on the floor. As this was off-licence use of vancomycin, the treatment was personally performed by the senior author twice daily for nine days. The pyrexia settled and after catheter removal the patient made a full recovery. He was discharged home 48 hours later with lifelong Augmentin following microbiology advice. He initially was reviewed with USG six monthly for three years then annually and remains well after eight years with no recurrence of infection.

DISCUSSION

Aortic graft insertion is complicated by infection in 0.5-2% of cases [1]. Late graft infection typically differs from early infection by culturing more indolent bacteria as the infectious organism. Bacteria such as Staphylococcus epidermidis are difficult to eradicate and may chronically infect aortic grafts without causing any symptoms. Vancomycin has been shown to be a suitable antibiotic for infected prosthetic grafts due to its bactericidal properties and efficacy against Methicillin-resistant Staphylococcus aureus infections [1].

The successful use of a non-antibiotic agent, 0.5% povidone-iodine and super acidic solution to irrigate aortic bed infection has been documented in a vascular case [2]. Antibiotic irrigation itself has been documented as a treatment for septic arthritis with joint space lavage and also to treat post-pneumonectomy empyema [3]. Schumaker and
Mandelbaum used vancomycin and povidone-iodine irrigation to treat mediastinitis, reducing mortality from 31% to 1.6% when compared to intravenous vancomycin alone [4].

Morris and colleagues reported a prospective study in which 10 patients with infected aortic grafts were treated with antibiotic irrigation via silicone drainage tubes placed around anastomoses. They used gentamicin as the initial antibiotic and then altered the agent according to cultures with an irrigation time ranging from 12 to 56 days. The results were promising; six out of seven survivors were free from infection at four to seven years [5].

**CONCLUSION**

Intracavity vancomycin irrigation for recurrent aortic bed infection led to complete resolution of retroperitoneal sepsis in this case. We suggest that this technique could be a useful adjunct to surgical debridement for resistant retroperitoneal sepsis causing resolution of symptoms through local absorption of antibiotics and irrigation of surface bacteria.
