ABSTRACT

Introduction: Blunt traumatic injuries can include polytrauma with extensive soft tissue injuries. Motor vehicle collision, motor cycle crashes, falls, assault, and pedestrians struck by automobiles are merely a few of several mechanisms by which trauma patients arrive in the emergency room. Case Report: During a systematic evaluation of a 50-year-old patient after a pedestrian versus automobile accident, head, chest, abdominal and pelvic computerized tomogram were obtained to evaluate her abdominal tenderness. Findings typically identified include injuries involving bone fractures, intracranial hemorrhage, intra thoracic and abdominal organ injuries. Incidental finding of congenital intestinal malrotation was seen on CT scans. Conclusion: We present an incidental finding of congenital intestinal malrotation in an adult patient after blunt force trauma.

Keywords: Malrotation, Trauma, Incidental findings

INTRODUCTION

Blunt traumatic injuries can include polytrauma with extensive soft tissue injuries. Motor vehicle collision, motor cycle crashes, falls, assault, and pedestrians struck by automobiles are merely a few of several mechanisms by which trauma patients arrive in the emergency room. The evaluation of these patients typically includes X-rays and Computed tomography (CA) scans to assess for occult injuries. Incidental findings are occasionally seen on CT scans. We present an incidental finding of congenital intestinal malrotation in an adult patient discovered after blunt force trauma. Malrotation usually presents in infants with abdominal wall defects and intestinal atresia, but occurs in association with Hirschsprung’s disease, gastroesophageal reflux disease (GERD), intussception or other congenital malformations [1]. Our patient was completely asymptomatic, and if it were not for computed tomography (CT) scan of her abdomen and pelvis, we would have been completely unaware of her anomaly.

CASE REPORT

A 50-year-old female without any significant past medical or surgical history presented to the emergency room after being involved in a pedestrian versus automobile accident. The physical exam was unremarkable. CT scans of her abdomen revealed that...
the cecum and ascending colon (Figure 1, arrow) were located predominately on the left side. Also, the superior mesenteric vein and the superior mesenteric artery were inverted in respect to their normal anatomic relationship with the superior mesenteric vein being located to the left of the superior mesenteric artery instead of to the right as in their normal anatomic configuration (Figure 2, arrow) which is a diagnostic of congenital malrotation. She was discharged after 24-hour observation and remained asymptomatic.

**DISCUSSION**

During prenatal development of the abdominal cavity, the midgut must undergo proper rotation to prevent the bowel from twisting on its vertical axis. These staged maneuvers occur during gestational development and usually present early in infancy if development does not follow its appropriate course. In the fourth to sixth week of gestational development, the abdominal cavity is unable to accommodate the quickly growing vissera and the midgut prolapses through the umbilical ring and into the umbilical cord. By the tenth to twelfth week of gestation, the midgut returns to the abdominal cavity and rotates 270 degree in a counterclockwise direction around the vertical axis of the superior mesenteric artery. Ultimately, the cecum is positioned in the right lower quadrant and the third portion of the duodenum and ligament of Treitz in the left upper quadrant [2]. Deviation or reversal of these synchronized movements during embryologic development may lead to several midgut anatomical variations including non-rotation, incomplete rotation, or incomplete fixation [3]. The precise mechanism of intestinal malrotation is not well understood, although genetic mutations may predispose to malrotation. The incidence of intestinal malrotation is approximately 1 out of 500 live births and is usually seen in infants [4].

However, rotational anomalies may present as obstructive symptoms from midgut volvulus, chronic abdominal pain or as an incidental finding as seen in our patient necessitating close observation only. If obstruction or ischemia is present Ladd’s procedure is a surgical option. Operative management for most symptomatic rotational anomalies includes Ladd’s procedure. This procedure involves lysis of the adhesive bands to mobilize the midgut, counterclockwise reduction of the volvulus, widening of the midgut mesenteric pedicle, and appendectomy. Entrectomy is performed only for necrotic bowel which in the presence of ischemic bowel may require performing a temporary abdominal closure with re-exploration in 24-36 hours [5].

**CONCLUSION**

Intestinal malrotation is a rare finding in adult patients and is usually found incidentally during radiographic imaging or surgical exploration for another disease process [6]. If the patient is symptomatic, further evaluation is needed to rule out bowel obstruction or mesenteric ischemia.
